

# Polkadot RE Spec

October 1, 2018

## 1 Conventions and Definitions

**Definition 1.** *Runtime* is the state transition function of the decentralized ledger protocol.

**Definition 2.** A **path graph** or a **path** of  $n$  nodes, formally referred to as  $P_n$ , is a tree with two nodes of vertex degree 1 and the other  $n-2$  nodes of vertex degree 2. Therefore,  $P_n$  can be represented by sequences of  $(v_1, \dots, v_n)$  where  $e_i = (v_i, v_{i+1})$  for  $1 \leq i \leq n-1$  is the edge which connect  $v_i$  and  $v_{i+1}$ .

**Definition 3.** **radix  $r$  tree** is a variant of a trie in which:

- Every node has at most  $r$  children where  $r = 2^x$  for some  $x$ .
- Each node that is the only child of a parent which does not represent a valid key is merged with its parent.

As the result, in a radix tree, any path whose interior vertices all have only one child and does not represent a valid key in the data set, is compressed into a single edge. This improves space efficiency when the key space is sparse.

**Definition 4.** The by a **sequences of bytes** or a **byte array**,  $b$ , of length  $n$ , we refer to

$$b := (b_0, b_1, \dots, b_{n-1}) \text{ such that } 0 \leq b_i \leq 255$$

We define  $\mathbb{B}_n$  to be the **set of all byte arrays of length  $n$** . Furthermore, we define:

$$\mathbb{B} := \bigcup_{i=0}^{\infty} \mathbb{B}_i$$

## 2 Block

In Polkadot RE, a block is made of two main parts, namely the *block header* and the *list of extrinsics*. The *Extrinsics* represent the generalization of the concept of *transaction*, containing any set of data that is external to the system, and which the underlying chain wishes to validate and keep track of.

## 2.1 Block Header

The block header is designed to be minimalistic in order to boost the efficiency of the light clients. It is defined formally as follows:

**Definition 5.** *The header of block  $B$ ,  $\text{Head}(B)$  is a 5-tuple containing the following elements:*

- **parent\_hash:** is the 32-byte Blake2s hash of the header of the parent of the block indicated henceforth by  $H_p$ .
- **number:** formally indicated as  $H_i$  is an integer, which represents the index of the current block in the chain. It is equal to the number of the ancestor blocks. The genesis block has number 0.
- **state\_root:** formally indicated as  $H_r$  is the root of the Merkle trie, whose leaves implement the storage for the system.
- **extrinsics\_root:** is the root of the Merkle trie, whose leaves represent individual extrinsic being validated in this block. This element is formally referred to as  $H_e$ .
- **digest:** this field is used to store any chain-specific auxiliary data, which could help the light clients interact with the block without the need of accessing the full storage. Polkadot RE does not impose any limitation or specification for this field. It essentially can be a byte array of any length. This field is indicated as  $H_d$

## 2.2 Justified Block Header

The Justified Block Header is provided by the consensus engine and presented to the Polkadot RE, in order for the block to be appended to the blockchain. It contains the following parts:

- **block\_header** the complete block header as defined in Section 2.1 and denoted by  $\text{Head}(B)$ .
- **justification:** as defined by the consensus specification denoted by  $\text{Just}(B)$  [\[link this to its definition from consensus\]](#).
- **authority Ids:** This is the list of the Ids of authorities, which have voted for the block to be stored and is formally referred to as  $A(B)$ . An authority Id is 32bit.

## 2.3 Extrinsics

Each block also contains a list of extrinsics. Polkadot RE does not specify or limit the internal of each extrinsics beside the fact that each extrinsics is a blob of encoded data. The `extrinsics_root` should correspond to the root of the Merkle trie, whose leaves are made of the block extrinsics list.

### 3 Entry into Runtime

## 4 API

### 4.1 Block Submission and Validation

Block validation is the process, by which the client asserts that a block is fit to be added to the blockchain. That is to say, the block is consistent with the world state and transitions from the state of the system to a new valid state.

Blocks can be handed to the Polkadot RE both from the network stack and from consensus engine.

Both the runtime and the Polkadot RE need to work together to assure block validity. This can be accomplished by Polkadot RE invoking `execute_block` entry into the runtime as a part of the validation process.

Polkadot RE implements the following procedure to assure the validity of the block:

**Algorithm 1**

```

IMPORT-AND-VALIDATE-BLOCK( $B$ , Just( $B$ ))
1  VERIFY-BLOCK-JUSTIFICATION( $B$ , Just( $B$ ))
2  Verify  $H_p(B) \in \text{Blockchain}$ .
3  State-Changes = Runtime.EXECUTE-BLOCK( $B$ )
4  UPDATE-WORLD-STATE(State-Changes)

```

### 4.2 Storage Access

## 5 State Storage and the Storage Trie

For storing the state of the system, Polkadot RE implements a hash table storage where the keys are used to access each data entry state. There is no limitation on neither the size of the key nor the size of the data stored under them, beside the fact that they are byte arrays.

To authenticate the state of the system, the stored data is re-arranged and hashed in a *radix 16 tree* also known as *base-16 modified Merkle Patricia Tree*, which hereafter we simply refer to as the **Trie**, in order to compute the hash of the whole state storage consistently and efficiently at any given time.

Also modification has been done in storing the nodes' hash in the Merkle tree structure to save space on entries storing small entries.

Because the Tri is used to compute the *state root*,  $H_r$ , (see Definition 5), which is used to authenticate the validity of the state database, Polkadot RE follows a rigorous encoding algorithm to compute the values stored in the trie nodes to ensure that the computed Merkle hash,  $H_r$ , matches across clients.

### 5.1 The General Tree Structure

As the trie is a radix 16 tree, in this sense, each key value identifies a unique node in the tree. However, a node in a tree might or might not be associated with a key in the storage.

To identify the node corresponding to a key value,  $k$ , first we need to encode  $k$  in a uniform way:

**Definition 6.** *The for the purpose labeling the branches of the Trie key  $k$  is encoded to  $k_{\text{enc}}$  using  $\text{KeyEncode}$  functions:*

$$k_{\text{enc}} := (k_{\text{enc}_1}, \dots, k_{\text{enc}_{2n}}) := \text{KeyEncode}(k) \quad (1)$$

such that:

$$\text{KeyEncode}(k): \begin{cases} \mathbb{B} & \rightarrow \text{Nibbles}_4 \\ k := (b_1, \dots, b_n) := & \mapsto (b_1^1, b_1^2, b_2^1, b_2^2, \dots, b_n^1, b_n^2) \\ & := (k_{\text{enc}_1}, \dots, k_{\text{enc}_{2n}}) \end{cases}$$

where  $\text{Nibble}_4$  is the set of all nibbles of 4-bit arrays and  $b_i^1$  and  $b_i^2$  are 4-bit nibbles which are the little endian representation of  $b_i$ :

$$(b_i^1, b_i^2) := (b_i \bmod 16, b_i / 16)$$

where  $\bmod$  is the remainder and  $/$  is the integer division operators.

By looking at  $k_{\text{enc}}$  as a sequence of nibbles, can walk the radix tree to reach the node identifying the storage value of  $k$ .

### 5.2 Node value

## 6 Parity Codec
